Heterogeneity and the Distance Puzzle*

Elizaveta Archanskaia[†] Guillaume Daudin[‡]

May 2012

Preliminary version - Comments welcome

Abstract

This paper shows that reduced heterogeneity of exporter-specific goods can provide a direct explanation of the distance puzzle. Using COMTRADE 4-digit bilateral trade data we find that the elasticity of trade to distance has increased by 8% from 1962 to 2009. Theoretical foundations of the gravity equation indicate that the distance coefficient is the product of the elasticity of trade costs to distance and a measure of heterogeneity, e.g. the substitution elasticity between exporter-specific goods in the Armington framework. This parameter has increased by 13% from 1962 to 2009. The evolution of the distance coefficient is thus compatible with a 4% reduction in the elasticity of trade costs to distance.

Keywords: gravity equation, distance puzzle, trade elasticity, trade costs

Introduction

The estimated effect of distance in gravity equations has remained stable, or even slightly increased, in the past 50 years.¹ This is the “distance puzzle”, as the common opinion is that technological developments in transports, e.g. the airplane and the container, had contributed to the “death of distance” (Cairncross (1997); Levinson (2006); Friedman (2007)).

Recent work on the distance puzzle has gone in two directions. Following Santos Silva and Tenreyro, one strand of the literature has sought to correct the estimation method using non linear estimators (Santos Silva and Tenreyro (2006); Coe et al. (2007); Bosquet and Boulhol (2009). See §I.2 for a discussion). The canonical log-linear estimation does not generally provide consistent coefficient estimates if the trade equation in levels is subject to heteroskedasticity. Furthermore, the log-linear estimation strategy suffers from sample selection bias because it cannot take into account nil trade flows. The growth of trade has been both intensive, in the sense that the volume of trade of established trade relations has increased, and extensive, in the sense that new trade relations have been established (Helpman et al. (2008); Baldwin and Harrigan (2007)). Taking zeros into account might change the evolution of the distance coefficient if new trade relations have in priority been established between distant partners. Using a non-linear estimator, Bosquet and Boulhol (2009) find that the distance elasticity of trade has been stable within the .6-.75 range between 1948 and 2006. Coe et al. (2007) find that it has decreased from 0.5 to 0.3 in 1975-2000.

The other strand of the literature has argued that there is no puzzle, as there are theoretical and empirical explanations of a non decreasing distance elasticity of trade (Bosquet and Boulhol (2009); Duranton and Storper (2008); Buch et al. (2004)). Firstly, a composition effect might explain a non decreasing distance coefficient. It might be that the composition of traded goods has changed toward goods which are either less transportable or which consumption is more sensible to trade costs. Theoretically, Duranton and Storper (2008) show how falling transport costs can induce firms into trading goods with higher transaction costs, leading to an increasing distance sensitivity of trade. Empirically, Berthelon and Freund (2008) test the impact of the changing composition of world trade between 1985 and 2005 on the distance coefficient, but

¹ Disdier and Head (2008) find that distance impedes trade by 37% more since 1990 than it did from 1870 to 1969 Berthelon and Freund (2008) find that the distance coefficient has increased by 10% in absolute value over the period 1985-2005. See also Bosquet and Boulhol (2009); Coe et al. (2007); Combes et al. (2006); Brun et al. (2005); Buch et al. (2004).

find that it has had a negligible effect.² Using a log-linear estimation strategy, Brun et al. (2005) and Márquez-Ramos et al. (2007) find decreasing distance elasticities once the sample is restricted to developed countries.

Secondly, it is not certain that transport costs have declined relative to the price of traded goods (Hummels (1999); Daudin (2003, 2005); Hummels (2007)). Furthermore, it might be the case that other distance-related components of trade costs, such as delays, have a growing importance (Hummels and Schaur (2012); Hummels (2001)).

Thirdly, the value of the distance coefficient in theoretically derived gravity models of trade is not directly related to the level of trade costs.³ It is the product of two elasticities: the elasticity of trade flows to distance-related trade costs, and the elasticity of trade costs to distance. Whether transport costs have declined or increased, the crucial question for the evolution of the coefficient is whether non-distance dependent transport costs, such as loading costs at ports, have declined relatively to distance-dependent transport costs, such as fuel costs (Feyrer (2009)).

The discussion on the distance puzzle in this second strand of the literature has been mainly concerned with the evolution of the elasticity of trade costs to distance. One should look as well at the elasticity of trade flows to trade costs. Following ?, we refer to this parameter as the ‘trade elasticity’. The structural interpretation of the trade elasticity depends on the micro foundations used to derive the gravity equation: in the canonical models this paper builds on, it corresponds alternatively to the dispersion in productive efficiency across sectors, to elasticities of substitution between country-composite goods, or to the intrasectoral dispersion in firm productivity. In all cases, the trade elasticity is inversely linked to the measure of heterogeneity in some dimension.

For example, since the 1960s, a number of countries have demonstrated their ability to produce the same set of goods as developed countries. This may have resulted in more uniformity in country-specific varieties. In the Armington framework this could have resulted in an increased elasticity of substitution between country-specific composite goods, and hence increased elasticity of trade flows to trade costs, providing a direct explanation of the distance puzzle (See the Anderson and van Wincoop (2003) derivation of the gravity model which uses the demand framework pioneered by Armington (1969). See §II.2 for a discussion). In the

² Berthelon and Freund find that 39% of products and 54% of trade has become more sensitive to distance over this period against 2.8% of trade becoming less sensitive to distance.

³ The level of trade costs, captured by country-specific fixed effects, influences the openness of each country.

Ricardian framework, it could be argued that countries' technological capabilities have become more homogeneous across sectors overtime which would result in reducing the strength of comparative advantage in determining trade flows, leading to an increased sensitivity of trade flows to trade costs (Eaton and Kortum (2002).). In the framework of monopolistic competition with heterogeneous firms, a reduced efficiency dispersion of firms within any given sector, i.e. a relatively bigger share of firms situated near the export threshold, could have increased the sensitivity of trade flows to trade costs (Chaney (2008).).

The data required to compute annual trade elasticities in 1962-2009 in the Ricardian and heterogeneous firms frameworks is unavailable.⁴ Therefore, this paper's original contribution is to investigate whether the evolution of the trade elasticity parameter in the Armington framework provides a direct explanation of the distance puzzle. We find that the elasticity of substitution between country-specific composite export goods (i.e. the aggregate trade elasticity in the Armington framework), once instrumented, has increased by at least 13% from 1962 to 2009. Two conclusions follow. First, the non-decreasing distance elasticity of trade is fully explained by the increase in the elasticity of trade flows to trade costs. Second, the distance puzzle ceases to exist insofar as the elasticity of trade costs to distance is found to have decreased by 4% from 1962 to 2009.

I The distance puzzle in our data

As shown by Disdier and Head (2008), estimates of the distance elasticity are sensitive to the set of data used. This section measures the distance puzzle in our data and evaluates whether some combination of the factors identified by previous studies as explanatory of movements in the distance coefficient pins down the determinants of the distance puzzle. We focus on:⁵

- the composition effect defined as the evolution in the goods' composition of world trade;
- the sample effect which covers two types of developments: the formation of new trading relationships between previously existing countries; and the formation or disappearance of countries through dissolution of previously existing political entities;
- the selection into FTAs effect which corresponds to the formation of Free Trade Agreements between existing countries.

⁴ We refer the reader to the technical note available upon request from the authors for details.

⁵ Results on the impact of the estimation strategy are not reported because they are qualitatively similar to Bosquet and Boulhol (2009).

I.1 Data

We use the COMTRADE world bilateral trade dataset spanning the years 1962-2009⁶. We use the 4-digit SITC Rev.1 classification of goods (600-700 goods), as this provides the longest coverage of disaggregated bilateral trade flows. We restrict the sample to trade in goods which are attributed to specific 4-digit categories. As trade data is of better quality for imports, the estimation is conducted only on import flows. Our sample covers between 88% and 99% of reported trade in COMTRADE.

Data on bilateral distance, bilateral trade costs' controls such as adjacency, common language, colonial linkages, and data on belonging or having once belonged to the same country is taken from the CEPII.⁷ We constructed the database on GATT/WTO and FTA membership.⁸

I.2 Methodology

The main theoretical derivations of the gravity trade model, e.g. Anderson and van Wincoop, Eaton and Kortum, and Chaney result in a qualitatively similar estimation equation for aggregate bilateral trade flows.⁹

Working with bilateral cross-section imports data, assuming that fixed bilateral trade costs are not a function of distance while certain components of variable trade costs can be modelled as a function of distance: $\tau_{ij} = dist_{ij}^p$, the three frameworks result in (1):

$$X_{ij} = \exp(\alpha_0 - \alpha_1 \ln dist_{ij} + \beta_1 Z_1 + \beta_2 Z_2 + fe_{exp} + fe_{imp}) \varepsilon_{ij} \quad (1)$$

X_{ij} is the value of goods from country i consumed in country j , e.g. imports at cif prices; $dist_{ij}$ is bilateral distance, Z_1 comprises bilateral trade costs' controls such as adjacency, common language, colonial linkages, belonging or having once belonged to the same country; Z_2 comprises bilateral trade cost controls linked to trade policy such as common membership of GATT/WTO and common membership of an FTA; fe_{exp} and fe_{imp} are respectively exporter and importer

⁶ The 228 trading partners present in this dataset are listed in App.B.

⁷ See Mayer and Zignago (2011). The database is available at www.cepii.fr. We constructed bilateral distance and bilateral costs' controls for East and West Germany, USSR, and Czechoslovakia.

⁸ Data for membership of GATT/WTO was taken from the WTO website http://www.wto.org/english/thewto_e/gattmem_e.htm. Data for common membership of an FTA was constructed on the basis of Crawford and Fiorentino (2005), Fontagné and Zignago (2007), and the RTA Information System on the WTO website <http://rtais.wto.org/UI/PublicMaintainRTAHome.aspx>. See App. A for the list of included FTAs and the years they appear in our data.

⁹ See footnote 20 in Eaton and Kortum (2002) for a discussion of the equivalence of the resulting equations in the Ricardian framework, in Armington framework such as Anderson and van Wincoop (2003), and in monopolistic competition models such as Krugman (1980), extended by Chaney (2008) to the setting of heterogeneous firms.

fixed effects, and ε_{ij} is a multiplicative error term.

Santos Silva and Tenreyro have shown that slope estimates from the log linear estimation of equation (1) will generally be biased because the trade equation in levels is subject to heteroskedasticity. They argue that the structure of trade data is such that in general the additive error term in the log-linearized model is heteroscedastic, and its variance depends on the regressors. In this case, OLS does not generally give consistent slope estimates (See Manning and Mullahy (1999); Santos Silva and Tenreyro (2006)). Santos Silva and Tenreyro advocate the use of the Poisson pseudo maximum likelihood (PPML) estimator. It is likely to be an efficient estimator because it assumes that the conditional variance of the raw data is proportional to the conditional mean. This fits trade data better than the assumption that the conditional variance is independent of the regressors made with the NLS estimator.¹⁰

A non-linear estimator such as the PPML has the additional advantage of including zero trade observations in the estimation.¹¹ However, its implied functional form is not consistent with the prevalence of zero trade observations. There are two possible approaches to zero trade flows. The two-stage approach, followed by Helpman et al. (2008) is to modify the theoretical model to generate zero trade flows. They achieve this in a setting with heterogeneous firms with bounded support distribution.¹² The alternative, two-part approach, followed in this paper, is to stay within the three canonical frameworks which do not allow for zero trade flows, and to treat such observations as a statistical problem due to data registration thresholds.¹³ Nil trade flows correspond to underlying positive flows which are below the data collection threshold.¹⁴ The two-part model deals adequately with the sample selection bias, and is consistent with the underlying model. Specifically, we couple the PPML estimator with a logit estimation of the

¹⁰ The general structure of the conditional variance function in the generalized linear model is: $Var[y_i|x] = \lambda_0 \mu(x_i\beta)^{\lambda_1}$. The NLS corresponds to $\lambda_1 = 0$, the PPML to $\lambda_1 = 1$, and GPML to $\lambda_1 = 2$. The Gamma PML estimator is a valid alternative to PPML in terms of the assumption made on the underlying conditional variance function. But it performs worse than PPML because it is sensitive to certain forms of measurement error such as the rounding of the dependent variable. Santos Silva and Tenreyro (2006); Bosquet and Boulhol (2009) get qualitatively similar results in terms of GPML sensitivity to measurement error and NLS inefficiency.

¹¹ Helpman et al. (2008) show that ignoring zero trade flows in the loglinear specification induces a downward sample selection bias due to the negative correlation of unobserved and observed components of variable trade costs for pairs with non-zero trade flows. In our data, a Vuong test indicates that the number of zero trade observations is excessive and that a ZIP specification is preferable to a PPML one.

¹² Following this approach, the equation estimated in the second stage has to be augmented with a term which controls for the pair-specific fraction of exporting firms. See Helpman et al. (2008).

¹³ Mullahy (1986) showed that two-stage and two-part models give qualitatively similar results when there is clarity on the first-stage selection variable. The two-part approach performs better if there is uncertainty on the choice of the selection variable.

¹⁴ In the framework with heterogeneous firms this corresponds to the assumption of no upper bound on the productivity distribution or to an upper bound on productivity combined with sufficiently low fixed costs of trade.

chances of being in the zero category by doing a zero-inflated Poisson regression (ZIP).¹⁵

The baseline PPML regression includes bilateral distance, bilateral costs' controls, and country fixed effects.¹⁶ We find that α_1 , the absolute value of the distance coefficient, has increased over 1962-2009 (see Fig.1). There is indeed a distance puzzle.

Figure 1: Distance coefficient in the baseline PPML regression

Figure 2: Distance coefficient in the logit baseline ZIP regression (first part)

¹⁵ For details on the ZIP specification, see Greene (2003), p. 750. The name comes from Lambert (1992). It is named ‘With zeros’ model by Mullahy (1986) and ‘Zero-Altered Poisson’ by Greene (1994). This approach is advocated in Burger et al. (2009) and in Martin and Pham (2008). For a critical approach of the ZIP, see the page of J.M.C. Santos Silva at <http://privatewww.essex.ac.uk/~jmc/ss/LGW.html>.

¹⁶ $M_{ij} = \exp(\alpha_0 - \alpha_1 \ln dist_{ij} + \beta_1 Z_1 + fe_{exp} + fe_{emp}) \epsilon_{ij}$.

Figure 3: Coefficient of partial determination in the PPML baseline equation

The two-part model uses the same set of explanatory variables in the first step (logit) and in the second step (PPML restricted to predicted non-zeros) as the baseline PPML regression. This estimation procedure allows circumscribing the distance puzzle. We find that the distance coefficient in the logit regression has decreased, i.e. the formation of a trading relationship is less sensitive to distance (see Fig. 2). The second step of the ZIP regression gives qualitatively very similar results to the baseline PPML regression (see Table 1). We conclude that the distance puzzle is specific to existing trade relationships. Conditional on trading, trade volumes have become more sensitive to distance since 1962. However, the ZIP method has an important drawback: convergence of the estimation is difficult to achieve consistently over all years, and especially in the 1980s. For this reason, in the rest of this section we show results obtained with the PPML estimator while Table 1 evidences that results are not sensitive to this choice.

The amount of trade variance explained by distance does not have any trend over the whole period. The partial coefficient of determination, or the marginal contribution of distance to the coefficient of determination, has steadily declined from the late 1970s to 2000, yet it is in the late 2000s at the same level as in the 1960s (see Fig. 3).

I.3 Robustness of the distance puzzle

To verify the robustness of the distance puzzle, we estimate three variants of the baseline regression. First, entry and exit of countries in the sample could drive the increasing sensitivity of trade flows to distance. To test this, we restrict the sample to trading partners which have

non-zero trade both ways in every year over 1962-2009. This leaves 786 stable two-way pairs.¹⁷

Fig. 4 shows that the sample effect does not reduce the distance puzzle.

Figure 4: Distance coefficient in sample of stable pairs (PPML)

Second, the changing composition of trade in terms of goods could explain the distance puzzle. To compute the impact of the composition effect, trade shares of each good in total trade are fixed at their 1962 values. As shown by Fig. 5, the composition effect deepens the distance puzzle.¹⁸

Contrasting both Fig. 4 and Fig. 5 with Fig. 1, it is interesting to remark that most short-term fluctuations of the distance coefficient seem to be explained by sample and composition effects.

Third, we check whether controlling for countries' selection into FTAs and GATT/WTO membership reduces the distance puzzle. Separate controls are included for each FTA.¹⁹

As shown in Fig. 6, controlling for countries' participation into free trade agreements solves the distance puzzle. However, this effect is mechanical. Fig. 7 shows that the share of intra-FTA trade among nearby (less than 2000 km) countries has increased from 38% in 1962 to

¹⁷ This is a rectangular sample which includes 32 countries: Argentina, Belgium-Luxembourg, Brazil, Canada, Chile, Colombia, Denmark, France, Germany, Great Britain, Greece, Hong Kong, Iceland, Israel, Italy, Japan, Malaysia, Mexico, Netherlands, Philippines, Portugal, Paraguay, Singapor, South Korea, Spain, Sweden, Switzerland, Thailand, Tunisia, Turkey, Venezuela and the USA. China, India, Sub-Saharan African, Central and Eastern European countries do not have a reciprocal trading relationship in all years with any single country, and are thus excluded.

¹⁸ Robustness checks have been conducted using 1984 and 2009 weights. Results are qualitatively similar.

¹⁹ See Appendix A for the full list of included FTAs. Restricting this list to the "main" FTAs (EC and EU, USA-Canada FTA and NAFTA, the Comecon, EFTA, ASEAN, Mercosur, as well as GATT-WTO) leads to the same result.

Figure 5: Distance coefficient controlling for composition (1962 weights)

Figure 6: Distance coefficient controlling for FTAs (full sample)

79% in 2009, whereas in-FTA trade has increased from less than 20% of total trade to approximately 40%.²⁰ The inclusion of controls for FTA membership thus amounts to adding a growing number of proximity controls in the regression. This reduces the sensitivity of trade flows to distance. A further argument for caution in interpreting results with FTA controls is the probable endogeneity of FTAs for which we do not correct in our estimation. In this respect, Bosquet and Boulhol (2009) show that the distance coefficient evolves in the same way when they do not control for FTAs (fig. 9 in their paper) and when then control for FTAs correcting

²⁰ Trade at less than 2000 km corresponds to the first decile of the distance distribution of trade in 1962-2009.

for endogeneity (fig. 11 in their paper).

Figure 7: Share of intra-FTA trade among nearby countries (2000km or less)

Table 1 summarizes our findings on the distance puzzle. Controlling for sample, composition, or the combined sample-composition effects does not change the magnitude of the distance puzzle whereas controlling for FTAs does. As argued, the explanation of the distance puzzle through FTAs is not satisfactory because this amounts to adding a growing number of proximity controls in the regression and because FTAs are endogenous to trade intensity. We conclude that the distance puzzle is robust, and that the traditional approach is little informative of the driving forces behind the increased sensitivity of trade flows to distance. The main contribution of this paper is the alternative approach to identifying the determinants of increased sensitivity of trade flows to distance to which we turn next.

Table 1: Evolution of the distance coefficient depending on sample, composition, FTA effects

	% change relatively to baseline		Total change 1962-2009	
	PPML	ZIP	PPML	ZIP
Baseline			1.07	1.08
Sample effect	7%	5%	1.14	1.14
Composition effect	7%	6%	1.14	1.15
FTA effect	-54%	-52%	0.49	0.52
Composition + sample	7%	5%	1.14	1.14
Composition + FTA	-29%	-29%	0.75	0.77
Sample + FTA	-59%	-59%	0.44	0.44
Sample + Composition + FTA	-54%	-55%	0.49	0.49

Results reported in the last two columns correspond to a geometric trend.

II Interpreting the distance coefficient

The distance coefficient, or the elasticity of trade to distance, is the product of two elasticities: the elasticity of trade costs to distance and the elasticity of trade flows to trade costs. The three main microfoundations of the gravity model of trade give structurally different interpretations to the elasticity of trade flows to distance.

II.1 The three main microfoundations

In Eaton and Kortum (2), consumers shop around the world for the cheapest supplier of each sectoral good. Bilateral exports are a function of total sales of exporter i , of total expenditure of importer j , as well as of the total world market as perceived by exporter i . Bilateral exports are also a function of bilateral trade barriers of exporter i with importer j , and of the price index (p_j) of the importer. The parameter θ captures the degree of heterogeneity in productive efficiency within countries across goods, i.e. the strength of comparative advantage. A higher value of this parameter generates less heterogeneity in domestic producers' efficiency across the set of goods. Comparative advantage exerts a weaker force against trade resistance imposed by trade barriers: the elasticity of trade to trade costs is higher in absolute value.²¹

$$X_{ij} = \frac{\left(\frac{\tau_{ij}}{p_j}\right)^{-\theta} Y_i Y_j}{\sum_{n=1}^N \left(\frac{\tau_{in}}{p_n}\right)^{-\theta} Y_n} \quad (2)$$

In Chaney (3), consumers value the varieties of goods produced by heterogeneous firms in a monopolistic competition setting. Bilateral exports are a function of the share of expenditure μ on goods which trade is costly,²² the nominal income of trading partners, world income, fixed and variable bilateral trade costs (f_{ij} and τ_{ij} , respectively), workers' productivity in the exporting country w_i , and a measure of importer's remoteness θ_j .²³ The parameter γ is the shape parameter of the Pareto distribution. It measures the degree of firm productivity heterogeneity in the costly-trade sector. The elasticity of trade to variable trade costs no longer depends on consumer preferences in the heterogeneous firms' framework. Rather, it is firms' efficiency dispersion which determines the aggregate trade elasticity: the lower the degree of efficiency

²¹ See Eaton and Kortum (2002).

²² The remaining expenditure is allocated to the numeraire sector producing a homogeneous freely tradable good.

²³ This remoteness measure is reminiscent of MR terms in Anderson and van Wincoop (2003), but it also accounts for firm heterogeneity in productivity and fixed bilateral trade costs. See Chaney (2008).

dispersion in domestic markets, the higher the trade elasticity.²⁴

The intuition for this result is given in Chaney (2008). The parameter γ is increasing in the fraction of small size low-productivity firms. If firms' efficiency dispersion is relatively low, the efficiency cut-off above which firms are able to acquire export status is in proximity of a substantial mass of firms. A reduction in trade barriers decreases the cut-off productivity needed to acquire exporter status, and this triggers entry of relatively many firms into exporting: lower efficiency dispersion among firms corresponds to an amplification of the aggregate trade elasticity through the extensive margin.²⁵ The degree of substitutability between firm-level varieties is measured by σ_f .

$$X_{ij} = \mu \frac{Y_i Y_j}{Y} \left(\frac{w_i \tau_{ij}}{\theta_j} \right)^{-\gamma} f_{ij}^{-\left(\frac{\gamma}{\sigma_f - 1} - 1\right)} \quad (3)$$

In Anderson and van Wincoop (4), there is no intersectoral or intrasectoral heterogeneity in productive efficiency. The heterogeneity dimension comes from the assumption that goods produced by different countries are not homogeneous. Each country is specialized in production of country-specific varieties which on aggregate give a country-specific composite good. Bilateral exports X_{ij} are a function of the nominal income of each trading partner $Y_{i,j}$, of world income Y , of bilateral trade costs τ_{ij} , and of multilateral trade resistance terms Π_i, P_j .²⁶ The parameter σ is the 'lower tier' Armington elasticity of substitution which measures the degree of substitutability of goods of different national origin (The 'upper-tier' elasticity pertains to substitutability of domestic products and an aggregate import good while the 'lower-tier' elasticity measures substitutability between importers of a given good: Sato (1967); Reinert and Shiells (Reinert and Shiells); Saito (2004)).²⁷

$$X_{ij} = \left(\frac{Y_i Y_j}{Y} \right) \left(\frac{\tau_{ij}}{\Pi_i P_j} \right)^{-(\sigma-1)} \quad (4)$$

To sum up, all theoretical frameworks used to derive the gravity equation are characterized by a common feature: the elasticity of trade flows to trade costs, the 'trade elasticity', is de-

²⁴ See the technical appendix to Chaney (2008) for the proof that the elasticity of trade flows to variable trade costs is common across countries and equal to γ under the small country assumption.

²⁵ Productivity is distributed over $[1, +\infty)$ as follows: $P(\tilde{\phi}_k < \phi) = \mathcal{G}_k(\phi) = 1 - \phi^{-\eta}$ where ϕ is unit labour productivity. Firm-specific productivity determines the marginal cost of production ($c_i = w_i/\phi$) where the wage w_i is pinned down by country-specific labor productivity in the numeraire sector.

²⁶ Π_i, P_j are respectively inward and outward MR terms.

²⁷ See Anderson and van Wincoop (2003). In monopolistic competition with homogenous firms the trade elasticity parameter corresponds to the substitution elasticity between firm-level varieties (Dixit and Stiglitz (1977); Krugman (1980)). The structure of the equation would be similar, however.

creasing in the degree of heterogeneity observed in a single dimension, and it is this dimension which is framework-specific.²⁸ The coefficient of interest α_1 from equation (1) has a different structural interpretation in each framework:

$$\alpha_1^{ARMINGTON} = \rho(\sigma - 1); \alpha_1^{RICARDO} = \rho\theta; \alpha_1^{HET-FIRMS} = \rho\gamma.$$

II.2 What do we know about the evolution of heterogeneity?

In the investigation of the distance puzzle, we focus on the evolution of the heterogeneity parameter measured on aggregate trade data because, as shown by Imbs and Méjean (2011), trade responsiveness measured on aggregate data cannot be mimicked by a theoretically grounded weighted average of sectoral elasticities of substitution. This amounts to constraining sectoral substitution elasticities to equality.

The heterogeneity parameter measured on aggregate trade data could change without any changes in the degree of underlying heterogeneity. Three main factors could play a role.²⁹ First, the expansion in the range of traded goods could drive changes in measured heterogeneity. This explanation is valid across frameworks. Second, aggregation specific issues linked to estimating a single parameter across sectors potentially characterized by varying degrees of fundamental heterogeneity could evolve overtime, either due to intra-sectoral changes, or to changes in the range of traded goods. This explanation is relevant for frameworks allowing for sector specific parameters, i.e. the Armington and the heterogeneous firms' framework. Third, strategies adopted by economic agents in order to adapt to a changing economic environment, such as a reduction in trade barriers, could lead to endogenous changes in heterogeneity. This explanation is particularly relevant in firm heterogeneity models which allow for endogenous innovation.

There is relatively little empirical evidence on the evolution of both sector-specific and aggregate trade elasticities overtime. Three theoretically grounded methodologies have been used to estimate aggregate trade elasticities in the Ricardian framework for a specific year (Eaton and Kortum (2002); Simonovska and Waugh (2011); Costinot et al. (2012); Caliendo and Parro (2011)). Levchenko and Zhang (2011) is the only paper which studies the evolution of inter-sectoral productivity dispersion. They find evidence of within-country convergence in sectoral knowledge stocks in 1960-2010. As there is less heterogeneity in producers' efficiency across the set of goods, comparative advantage exerts a weaker force against trade resistance imposed

²⁸ See Arkolakis et al. (2012). See also the discussion in Chen and Novy (2011).

²⁹ We refer the reader to the technical note available upon request from the authors for details.

by trade barriers. In terms of the heterogeneity parameter, this result would be consistent with an increasing θ in 1960-2010, reducing the distance puzzle.³⁰

To the best of our knowledge, there is no direct empirical evidence on the evolution of sectoral or aggregate efficiency dispersion parameters in the heterogeneous firms framework.

Evidence on the evolution of lower-tier Armington elasticities of substitution measured on aggregate data is close to none. For France, Welsch (2006) provides estimates of aggregate lower-tier Armington elasticities since the 1970s. He finds that among exporters to the French market the elasticity peaked in the 1970s, and progressively decreased in the 1990s. Broda and Weinstein (2006) provide evidence on the evolution of sectoral Armington lower-tier elasticities between 1972-1988 and 1990-2001 for American imports. They find that they have decreased for all types of goods, and at all levels of product disaggregation, e.g. at the 10-digit, 5-digit, and 3-digit levels. These results indicate that the parameter estimated on aggregate trade data would also have decreased, deepening the distance puzzle. But to the best of our knowledge, no paper has as yet provided evidence on the evolution of Armington elasticities for aggregate bilateral trade while constraining the parameter to be the same across destination markets.

II.3 Which heterogeneity can be measured over the whole period?

To explore the distance puzzle defined as the non-decreasing distance elasticity of trade flows in 1962-2009, we need data which covers this whole period. It turns out that the only available source of data which covers the majority of countries over 1962-2009 is the UN COM-TRADE bilateral trade database which gives information on trade flows and unit values at the SITC 4-digit level.

Here we show that this information is sufficient to estimate the aggregate trade elasticity parameter in the Armington framework. The first step is to apply to this sectoral data a consistent aggregation procedure to get relative prices of country composite goods. The second step is to estimate the substitutability parameter for total bilateral trade using these relative prices.

Our data does not allow estimating the trade elasticity parameter in the Ricardian or the Melitz-Chaney framework because it does not contain information on domestic prices in the destination. The intuition for this result is the following: the threshold which determines the fraction of firms which enter any market is destination-specific. Therefore, the price distribution in each destination across all sources is needed to estimate the shape parameter of the

³⁰ In Levchenko and Zhang (2011) reduced dispersion in sector-specific technology stocks is obtained under the assumption of a constant θ , so it is not possible to interpret their results as evidence of a change in θ .

productivity distribution.³¹ In the Armington model, producer heterogeneity is not modelled, and the source-specific cost component gives directly the price of the exported good. The trade elasticity parameter can thus be estimated using only source-specific price distributions.

Define aggregate imports from source i as the sum of imports from each sector k where a sector corresponds to a SITC 4-digit category: $X_{ij} = \sum_k X_{ij}(k)$.³² Given CES utility at the intersectoral level, sectoral demand in j in sector k is given by:

$$Y_j(k) = \left(\frac{P_j(k)}{P_j} \right)^{-(\sigma-1)} Y_j$$

Assume each country exports a specific national variety. Preferences within each sector k between national varieties are assumed well represented by a CES utility function. Intrasectoral demand for varieties exported by i in j in sector k is:

$$X_{ij}(k) = \left(\frac{P_{ij}(k)}{P_j(k)} \right)^{-(\sigma_k-1)} Y_j(k)$$

Replacing $Y_j(k)$ by its value gives:

$$X_{ij}(k) = \left(\frac{P_{ij}(k)}{P_j(k)} \right)^{1-\sigma_k} \left(\frac{P_j(k)}{P_j} \right)^{1-\sigma} Y_j \quad (5)$$

Under the assumption that $\sigma_k = \sigma'$ in all sectors and $\sigma' = \sigma$:

$$X_{ij}(k) = \left(\frac{P_{ij}(k)}{P_j} \right)^{1-\sigma} Y_j$$

Summing over all SITC 4-digit sectors:

$$\begin{aligned} \frac{1}{Y_j} \sum_{k=1}^K X_{ij}(k) &= \frac{1}{P_j} \sum_{k=1}^K (P_{ij}(k))^{1-\sigma} \\ \frac{X_{ij}}{Y_j} &= \left(\frac{P_{ij}}{P_j} \right)^{1-\sigma} \end{aligned}$$

Going back to the expression for $X_{ij}(k)/Y_j$, use (5) to write:

$$\frac{X_{ij}(k) Y_j(k)}{Y_j(k) Y_j} = \left(\frac{P_{ij}(k)}{P_j(k)} \right)^{1-\sigma} \left(\frac{P_j(k)}{P_j} \right)^{1-\sigma}$$

³¹ We refer the reader to the technical note available upon request from the authors for details.

³² When several quantity units are observed, the sector is defined at the product*qty-unit level.

Replacing $\frac{P_j(k)}{P_j}$ by its value and defining $\frac{Y_j(k)}{Y_j} = \omega_j(k)$, we get:

$$\frac{X_{ij}(k) Y_j(k)}{Y_j(k) Y_j} = \left[\frac{P_{ij}(k)}{P_j(k)} (\omega_j(k))^{1/1-\sigma} \right]^{1-\sigma}$$

Summing over all SITC 4-digit sectors:

$$\sum_{k=1}^K \frac{X_{ij}(k) Y_j(k)}{Y_j(k) Y_j} = \sum_{k=1}^K \omega_j(k) \left[\frac{P_{ij}(k)}{P_j(k)} \right]^{1-\sigma}$$

Multiplying and dividing the right hand side of the expression by $\omega_j(k)^{1-\sigma}$ and taking logs:

$$\ln \left[\frac{X_{ij}}{Y_j} \right] = \ln \left\{ \sum_{k=1}^K \omega_j(k)^\sigma \left[\omega_j(k) \frac{P_{ij}(k)}{P_j(k)} \right]^{1-\sigma} \right\} \quad (6)$$

Working with the right hand side of (6), and using the approximation that for a large number of sectors k , $\ln \sum_k X_{k,ij} \approx \sum_k \ln X_{k,ij}$:

$$\ln \left\{ \sum_{k=1}^K \omega_j(k)^\sigma \left[\omega_j(k) \frac{P_{ij}(k)}{P_j(k)} \right]^{1-\sigma} \right\} \approx \sum_{k=1}^K \ln [\omega_j(k)^\sigma] + \sum_{k=1}^K \ln \left[\left(\omega_j(k) \frac{P_{ij}(k)}{P_j(k)} \right)^{1-\sigma} \right]$$

The first term disappears because:

$$\sigma \sum_k \ln \omega_{k,j} \approx \sigma \ln \left(\sum_k Y_{k,j} / Y_j \right) = \zeta \ln 1 = 0$$

Using the same approximation as previously for the second term:

$$(1 - \sigma) \sum_{k=1}^K \ln \left[\omega_j(k) \frac{P_{ij}(k)}{P_j(k)} \right] \approx (1 - \sigma) \ln \left[\sum_{k=1}^K \omega_j(k) \frac{P_{ij}(k)}{P_j(k)} \right]$$

The market share equation for aggregate bilateral trade as a function of the weighted average of sectoral relative prices of i in j is:

$$\ln \left[\frac{X_{ij}}{Y_j} \right] \approx -(\sigma - 1) \ln \left[\sum_{k=1}^K \omega_j(k) \frac{P_{ij}(k)}{P_j(k)} \right] \quad (7)$$

Exponentiating gives the equation to be estimated:

$$X_{ij}/Y_j = \exp \left[\lambda_0 - (\sigma - 1) \ln \left(\sum_k \omega_k \frac{P_{ij}(k)}{P_j(k)} \right) + fe_{exp} + fe_{imp} \right] \eta_{ij} \quad (8)$$

where fe_{exp} and fe_{imp} are source and destination fixed effects, η_{ij} is a multiplicative error term, and λ_0 is a constant. Source fixed effects control for the world preference for products of this origin. Destination fixed effects control for unobserved domestic prices. The PPML estimator

is used because of the heteroskedasticity of the market share equation in levels (See I.I.2.)

Using the properties of the CES aggregator and the assumption $\sigma' = \sigma$, the market share equation for aggregate bilateral trade can be written as function of the weighted average of sectoral relative prices of each source in the destination. Each sectoral relative price is weighted according to the share of the sector in total expenditure of the destination which means that identical weights are applied on both sides of the equation.³³

Using COMTRADE, source-specific sectoral prices $P_{ij}(k)$ are defined as the unit values of SITC 4-digit categories where these sectoral unit values are taken as a proxy for consistently aggregated cif prices of varieties exported within each sector k . Destination-specific sectoral prices $P_j(k)$ are constructed as a weighted average of observed unit values for each source in sector k where weights are given by the market share of each source in this sector in the destination: $P_j(k) = \sum w_{ij}(k)P_{ij}(k)$ with $w_{ij}(k) = X_{ij}(k)/Y_j(k)$. Exporters for which some trade but no unit value is observed in k are excluded from the computation of $P_j(k)$.

III Measuring the evolution of heterogeneity

III.1 Missing unit values

To estimate the market share equation on the COMTRADE dataset we need to tackle the question of missing information on trade flows and unit values (uv).

A first difficulty arises when the trade flow is observed but information on quantities is missing, and it is therefore not possible to compute the unit value. On average, lacking uv corresponds to 14% of total recorded trade in 1962-2009, with a gradual increase in coverage from 83% to 90% between 1962-2000, and a subsequent decrease back to 82% in 2001-2009.³⁴ We assume that information on quantities is missing due to imperfections in the data collection procedure, and that bilateral trade flows are observed with a similar degree of precision whether or not quantity had been recorded. To deal with missing uv, we impute prices from observed prices in “similar” sectors³⁵.

Our stepwise price imputation procedure is as follows. First, the relative price of each source in the destination is constructed at the highest disaggregation level for each product and quantity

³³ To see this, rewrite aggregate imports: $\frac{X_{ij}}{Y_j} = \sum_k \frac{X_{ij}(k)}{Y_j(k)} \frac{Y_j(k)}{Y_j}$ where $\frac{Y_j(k)}{Y_j} = \omega_j(k)$.

³⁴ Unit value coverage corresponds to a mean of 86% of total trade in 1962-2009, with a standard deviation of 2.4 percentage points. Annual uv coverage varies between 82-91%, with an increase from 83-85% in 1962-1973 to 86-87% in 1974-1983, and 87-90% in 1984-2000. In 2001-2006 it is 85-87%, and about 82% in 2007-2009.

³⁵ An alternative procedure consists in imputing the relative price observed for another source which has a similar market share in this sector and destination. Results are not sensitive to using this alternative procedure.

unit in which the source is active (which we call “4’-digit level”). Second, we proceed level by level for aggregation: the relative price of the composite sectoral good of the source is first constructed at the 4-digit level using the weighted average relative price observed at the 4’-digit level, with destination-specific weights for each variety of the 4’-digit good the source is active in. Given relative prices constructed at the 4-digit level, destination-specific weights are used to aggregate these up to the 3-digit level, and so on until the relative price for the composite good is constructed using relative prices at the 1-digit level. This improves the estimation of prices, if one assumes that missing destination-specific relative prices at the 4’-digit can be approximated by the mean observed destination-specific relative price among the corresponding 4-digit group (and similarly at each aggregation level).

III.2 Zero trade flows

A second difficulty arises when both quantity and trade data are missing. Zero trade flows (ztf) are a prevalent feature of the data while under model assumptions some trade should be observed in every sector k between all pairs ij .³⁶

We assume that this information is missing because the underlying trade flow is positive but so small that it does not pass the threshold applied by the data collecting authorities (in UN COMTRADE this threshold corresponds to 1000 USD). Such flows, if recorded, would not substantially modify the distribution of observed market shares in the destination (the left hand side of (8)), because they are an order of magnitude smaller than observed trade.

We use the same stepwise price imputation as in the case of missing unit values. This is problematic because the constructed relative price of the composite good systematically underestimates the true underlying relative price. Under model assumptions, statistically unobserved trade values must correspond to a higher cif price than the maximum observed price in the destination across all sources and sectors while by construction we postulate that unobserved relative prices in ztf sectors are equal to a weighted average relative price across sectors in which trade is observed.

The assumption we make on unobserved prices would not be problematic if the underestimation factor were constant across exporters.³⁷ This scalar would cancel out across sources,

³⁶ The share of observed SITC 4-digit flows relatively to the total number of potential SITC 4-digit bilateral trade flows increases from 10% to 14% in 1962-2009.

³⁷ An alternative method consists in imputing unobserved relative prices with some arbitrary price above the maximum observed in the destination. As ztf constitute 85-90% of all 4-digit trade flows, this method is problematic because results are driven by imputed rather than effectively observed prices.

and the estimated substitutability parameter would correspond to the true parameter. This is obviously not the case. Table 2 shows that the underestimation factor is not constant across exporters: the share of ztf is strongly decreasing in market share. The relative price of the composite good is underestimated by more for small exporters. For a given observed distribution of market shares, the underlying dispersion in relative prices of the composite good is greater than the observed dispersion in relative prices. The estimated parameter $\tilde{\sigma}$ overestimates the true substitutability parameter σ .

Table 2 shows that the reduction in the share of ztf proceeds at quicker pace in 1962-2009 for small exporters: the coefficient for the interaction term for the market share and year is significant and positive. Table 3 presents the predicted share of ztf for four types of exporters in 1962 and 2009. For a very small exporter with .02% market share, the initial share of ztf is predicted to be .95, and it is reduced to .83 by 2009, i.e. a 12 percentage point decrease. Consider a relatively big exporter, with a 10% market share: its share of ztf is reduced from .72 to .65, a 7 percentage point decrease. As the gap between the share of ztf for big and small exporters is reduced overtime, the overestimation bias of $\tilde{\sigma}$ is progressively reduced.

Table 2: **Proportion of zero trade flows as a function of market share**

depvar:				
Share of ZTF				
	(1)	(2)	(3)	(4)
ms	-0.0401*** (0.0001)	-0.2446*** (0.0134)	-0.0427*** (0.0001)	-0.2573*** (0.013)
year	-0.0029*** (0.0000)	-0.0020*** (0.0001)	-0.0033*** (0.0000)	-0.0024*** (0.000)
<i>ms * year</i>		0.0001*** (0.0000)		0.0001*** (0.000)
constant	5.3474*** (0.0335)	3.5852*** (0.1372)	6.0976*** (0.0366)	4.2515*** (0.134)
Destination FE	NO	NO	YES	YES
Observations	657001	657001	657001	657001

Notes: The share of ZTF is computed at the SITC 4-digit level. The estimation is conducted in PPML in order to include observations where ztf=0. The log of the market share is used in the estimation. Destination fixed effects are included in (3) and (4). Robust standard errors are in parentheses. *** p<0.01.

Table 3: **Predicted share of ztf for exporters with different market share, 4-digit level**

year	ms=0.02%	ms=1%	ms=10%	ms=28.7%
1962	0.95	0.80	0.72	0.69
2009	0.83	0.71	0.65	0.62

Columns (1) and (4) correspond to the mean and to 2 st. deviations above the mean in the distribution of log market share. Columns (2) and (3) correspond to the mean and to 2 st. deviations above the mean in the distribution of market share.

Thus, the hypothesis we make on unobserved sectoral prices in ztf sectors does not always impede interpreting the evolution of the underlying substitutability parameter. In particular, if it is found that the estimated parameter increases in absolute value, this evolution necessarily provides a lower bound on the increase in the underlying substitutability parameter. This is because the overestimation bias is reduced overtime.

Figure 8 presents the results on the evolution of $\tilde{\sigma}$ obtained when (8) is estimated on annual crosssections of the COMTRADE dataset. The absolute value of trade elasticity has increased by about 29% from 1962 to 2009.

Figure 8: Estimated $(1 - \tilde{\sigma})$

III.3 Robustness checks

III.3.1 Changing the dataset

We provide a robustness check by estimating the evolution of the heterogeneity parameter for aggregate bilateral trade on a different dataset. We use the BACI dataset which reports bilateral trade data at the HS-1992 6-digit disaggregation level for 1995-2009. The accuracy of the relative prices of country-composite goods constructed with this dataset is improved because the harmonization procedure applied by Gaulier and Zignago (2010) in constructing BACI yields much better-quality unit values while substantially reducing the number of observations with lacking unit value. As a result, at the 6-digit level, less than 7% of total reported trade in BACI has missing unit values. This is reduced to 1-3% of total trade when the data is aggregated to the 4-digit level, as opposed to more than 10% in the raw COMTRADE data we originally used. Another advantage is that the share of ztf in BACI is stable in 1995-2009 as opposed to relatively strong fluctuations in the share of ztf overtime in our original dataset. The disadvantage of BACI is that it covers only a relatively short period compared to the years over which the distance puzzle exists. Obviously, we do not expect to reproduce exactly the results obtained with our original dataset because the trade classification and its level of aggregation are different.

Figure 9: Estimated $(1 - \tilde{\sigma})$, BACI database

Fig. 9 shows that our results hold: the elasticity parameter is found to increase in absolute value from 1995-2009. This can be compared with the equivalent period in our original dataset: the increase in the elasticity is much steeper on the BACI dataset. This finding supports the idea that our benchmark estimation results likely provide a lower bound on the increase in the

aggregate trade elasticity. However, the level of the elasticity estimated in 1995-1999 on BACI data is puzzling and suggests the existence of an attenuation bias. This is the focus of our second robustness check.

III.3.2 Instrumenting: motivation and results

The results just presented are subject to caution if supply schedules are not horizontal.³⁸ In that case, the demand elasticity parameter estimated in the market share equation will suffer from attenuation bias due to not controlling for potentially positive and finite supply elasticities. This attenuation bias would not be problematic for analyzing the evolution of the substitutability parameter if only the level of the parameter were affected. The problem arises because, as shown by Feenstra (1994), the attenuation bias also impacts the evolution of the parameter.

Feenstra has developed an instrumental variables' approach which solves this problem (see Feenstra (1994), and refinements in Broda and Weinstein (2006) and Imbs and Méjean (2011)). This method exploits year-to-year variations in relative prices and market shares over 10- to 20-year estimation windows to compute the Armington elasticity. We refrain from this approach for two sets of reasons. First, Feenstra's method relies on the assumption that the elasticity parameter remains constant through time, whereas we want to allow the parameter to vary in each year. Second, more fundamentally, Feenstra's elasticity parameter determines short-run, marginal, longitudinal effects whereas we are interested in the elasticity parameter which determines long-run, equilibrium, cross-section outcomes. It is not immediate that these two elasticities should be the same.

In this paper, we opt for a different approach in order to preserve the time dimension which is central to our analysis. We would like to have an instrument which adequately captures exporter-specific shocks to the price of the composite good which are not demand-driven, such as exogenous shocks to inputs' prices. One possibility would be the Producer Price Index (PPI) since it captures the evolution of prices faced by producers on the inputs' side. Unfortunately, we do not have PPI data for most countries and years in our sample. We therefore settle for an alternative exporter-specific price level indicator: the GDP price level in current US dollars as reported in the Penn World Tables for 189 countries in 1950-2009.³⁹

³⁸ Broda et al. (2006) find evidence of non-horizontal supply schedules at the 4-digit disaggregation level. Magee and Magee (2008) provide evidence that the small country assumption may in fact hold in the data in which case there would be no attenuation bias.

³⁹ See Heston et al. (2011). Our sample of countries does not coincide perfectly with the countries in the Penn World Tables. However, as it is the smallest exporters which drop out, the sample adjustment in terms of world trade coverage is minor.

The instrumenting procedure is the following. First, we compute relative prices for exporter-specific composite goods in each destination market using the stepwise price imputation procedure (see III.1). Second, for each destination market, we compute the mean evolution of GDP price levels in current US dollars of its trading partners, weighted by their market shares in this destination. This amounts to computing the evolution of the relevant real exchange rate for each specific bilateral trade relation. Third, we compute a hypothetical relative price at time t for each exporter in each market as the product of its relative price at time $(t - 1)$ and the evolution of its GDP price level between t and $(t - 1)$ relatively to all other trading partners in this destination. Fourth, we predict the relative price of each exporter in each destination at time t by regressing its observed relative price on this hypothetical relative price. This gives an instrumented relative price for each exporter which depends only on its past relative price and the relative evolution of its GDP price level. Finally, we estimate (8) using these instrumented relative prices instead of the observed relative prices.

It could be argued that allowing for just one lag inadequately captures the temporal relationship between shocks to inputs' prices and their pass-through to the price of exported output. Indeed, if prices are relatively persistent, the instrumenting procedure would amount to little more than replacing observed prices in t with lagged observed prices in $(t - 1)$. We therefore also estimate (8) using as instrument the evolution of each exporter's GDP price level relatively to all other trading partners in the destination between $(t - s)$ and t where $s = 1, \dots, 10$.

Results obtained with one lag ($s = 1$) are shown in Fig.10. The absolute value of the substitutability parameter has increased by 13% in 1962-2009 while its level increases by 9% on average relatively to the estimate obtained with non-instrumented prices.

This result is robust to increasing the number of periods in which the evolution of exports' prices is predicted with the evolution of domestic prices (see Appendix C). Thus, for $s = 10$, the elasticity increases by 29% in 1972-2009 (compared to 26% for $s = 1$ over the same period). The evolution of the parameter becomes steeper as we increase the number of lags. Therefore, it is likely that our estimate provides a lower bound on the increase in the true substitutability parameter.

III.4 Is there a distance puzzle left?

This section has provided empirical evidence on the evolution of the aggregate substitutability parameter for world trade in 1962-2009. This substitutability parameter corresponds to the

Figure 10: Estimated $(1 - \tilde{\sigma})$, instrumented relative price of composite good, 1 lag

aggregate trade elasticity in the Armington framework. We find that this parameter has increased by 29% between 1962 and 2009 in the benchmark estimation, and by 13% when relative prices are instrumented. Both estimates are likely to be providing lower bounds on the increase in the true substitutability parameter. Section I has shown that the distance elasticity of trade has increased by 8% over the same period. Combining these two results to evaluate the magnitude of the distance puzzle redefined as increasing elasticity of trade costs to distance, we conclude that there is no distance puzzle in the framework of the Armington model in as much as the elasticity of trade costs to distance has decreased by 4% in 1962-2009. The increasing distance elasticity of trade is fully explained by increased perceived substitutability of country-specific composite goods.

What is the economic interpretation of an increasing substitutability parameter measured on aggregate data?

First, the degree of perceived similarity of country-composite goods may have increased. Since the 1960s, a growing number of countries started producing a set of goods similar to that of developed countries. This process has increased the number of available varieties and, potentially, their degree of similarity.⁴⁰

Second, composition effects may have lead to changes in the parameter estimated on aggregate data. If the reduction in trade barriers has led to the expansion in the range of traded goods, trade in previously non-traded sectors could modify measured substitutability of country-

⁴⁰ Schott (2004) documents increased similarity in the set of exported goods of US trade partners while Broda et al. (2006) document the increase in the number of imported varieties since the 1970s.

composite goods. Non-uniform reductions in sectoral trade costs would also modify the composition of world trade, leading to a change in the substitutability parameter measured on aggregate data.

Ideally, we would like to separate out the impact of composition and sector-specific effects to quantify the net effect of increased perceived similarity of country-composite goods. This is however impossible because, as shown by Imbs and Méjean (2011), the parameter estimated on aggregate data cannot be mimicked by a weighted average of sectoral parameters. The bottom line is that an increase in measured substitutability for country-composite goods is consistent with complex competition dynamics in price and quality documented by Amiti and Khandelwal (2012) as well as with increased vertical specialization of countries within sectors documented by Fontagné et al. (2008).

Conclusion

The estimated effect of distance in gravity equations has slightly increased in the past 50 years despite substantial innovation in transportation and communication: this is the ‘distance puzzle’. Using COMTRADE 4-digit bilateral trade data in 1962-2009, this paper finds that the evolution of the elasticity of trade flows to trade costs, referred to as the ‘trade elasticity’, provides a direct explanation of the increasing distance elasticity of trade. Increased sensitivity of trade flows to relative prices has more than compensated the reduction in the elasticity of trade costs to distance.

The paper proceeds in three steps. First, it shows that the distance puzzle is a feature of our data by estimating yearly cross-section gravity equations. In our baseline estimation the distance coefficient has increased by 8% from 1962 to 2009. This result qualitatively holds when we correct for changes in the sample of trading partners and the composition of world trade. Taking into account FTAs seems to solve the distance puzzle, but this is an artefact of their growing importance: introducing FTAs dummies amounts to adding a time-growing number of proximity controls in the estimation.

Second, the paper underlines that in the main theoretical foundations of the gravity equation the distance coefficient is the product of the elasticity of trade costs to distance and a measure of heterogeneity. In the Ricardian framework, heterogeneity is intra-country and inter-sector. The trade elasticity corresponds to the degree of dispersion in productivity within countries across goods. In monopolistic competition with firm heterogeneity, the dispersion parameter

is intra-country and intra-sector. The trade elasticity corresponds to the degree of dispersion in intrasectoral firm productivity. In the Armington framework, heterogeneity is inter-country and intra-sector. The trade elasticity corresponds to the degree of perceived substitutability of country-specific varieties of each good.

Third, the paper estimates the evolution of the trade elasticity in the Armington framework, i.e. the substitution elasticity between country composite goods. It uses 4-digit unit values as proxies for sectoral prices. In our method, unobserved unit values lead to an overestimation bias that is reduced over time. As the estimated elasticity still increases in absolute value this evolution provides a lower bound on the increase in the absolute value of the underlying trade elasticity. Once instrumented, the estimated elasticity increases by 13% between 1962 and 2009. The evolution of the distance coefficient is thus compatible with a decrease of the elasticity of trade costs to distance of at least 4%.

French Guiana	<i>R;P</i>	Norfolk Island	<i>P</i>		

The full sample contains 207 reporters (R) and 230 partners (P) which are listed in tables 4 and 5. ‘S’ indicates that the country is present in the superbalanced sample.

In the full sample, several countries shift from reporting trade on an individual basis to reporting trade jointly with another country. This is the case of Belgium and Luxembourg, as well as Eritrea and Ethiopia. For consistency, we use a single country identifier for each of these two pairs. A single country identifier is also used for Yougoslavia and for Serbia and Montenegro.

Figure 11: Trade coverage in the superbalanced sample

The superbalanced sample corresponds to the subsample of trading pairs which trade both ways in each and every year of the sample. This corresponds to 32 countries, and 786 reciprocal pairs out of the 992 possible pairs. To avoid discarding reported trade for pairs which have reciprocal trade, but would fall out of the sample because of countries’ split-up in several entities, or reunification, we introduce several additional single country identifiers before constructing the superbalanced sample. A single identifier is used for the Czech Republic, Slovakia, and Czechoslovakia; another single identifier for East, West, and reunited Germany; a single identifier for the USSR and the 15 countries which were formed after USSR split up. This brings Germany to the superbalanced sample, but the 15 countries which constituted the USSR still drop out because the USSR is never a reporter to COMTRADE. The Czech Republic and Slovakia also drop out because they do not have reciprocal trade in all years with another country of the sample.

As shown in Fig.11, the superbalanced sample covers 50-70% of full sample trade. Fig.12

shows the distribution of pairs in the full sample according to the number of years they are present in the sample.

Figure 12: Number of years each pair is present in the sample

As a check on the way the superbalanced sample is constructed, we redefine the set of pairs which trade both ways in each year starting from 1970, e.g. the first year in which there are more than 100 reporters in the COMTRADE database.⁴¹ This gives a sample of 1604 reciprocal pairs out of the 2162 possible pairs for 47 reporters (partners). Fig.13 shows that evolution of trade coverage is qualitatively similar.

Fig.14 shows the share of total trade covered by pairs which traded both ways in 1962, and as a check, the share of total trade by pairs which traded both ways in 1970. Qualitatively, trade coverage is similar to the superbalanced samples for, respectively, 1962 (1970). In the same figure, it is shown that one-way trade flows represent a marginal and decreasing share of world trade: more than 95% of total annual trade takes place between pairs which trade both ways in that year. This finding is complementary to Helpman et al. (2008) who find that the increase in world trade is driven by pairs which trade both ways in 1970. Helpman et al. (2008) find that the enlargement of the set of trading partners did not contribute in a major way to the growth of world trade in 1970-1997. We nuance this finding by showing that trade between partners who did not trade both ways in 1962 (1970) did contribute strongly to the increase in total trade in 1995-2009. Furthermore, these new trade relationships were formed between countries trading both ways. Part of the explanation of the widening gap between the superbalanced and

⁴¹ There are 71 reporters in 1962, and 112 in 1970.

Figure 13: Trade coverage in superbalanced sample defined in 1970-2009

the full sample in the recent period is linked to the absence of Central and Eastern European countries and of China from the superbalanced sample as these countries did not report trade to COMTRADE until the recent period.

Figure 14: Trade coverage in superbalanced sample defined in 1970-2009

C Robustness checks for instrumented prices

This appendix shows that our results on the evolution of the substitutability parameter in the estimation with instrumented prices are robust to increasing the number of periods s for which the growth rate in the relative price of the exported composite good is predicted on the evolution of relative domestic prices.

Fig.(15) shows that, as we increase s from 3 to 5, the evolution of the estimated substitutability parameter becomes steeper, and the increase in the level of the parameter becomes more stable across the years. Thus, for $s = 5$, the parameter is found to increase by 18% in 1967-2009 while its level increases by 20% on average relatively to the estimate obtained with observed relative prices.

Figure 15: Estimated $(1 - \tilde{\sigma})$, instrumented relative price of composite good

For $s = 10$, the substitution elasticity increases by 29% in 1972-2009, and the absolute value of the parameter increases by 22% on average relatively to the estimate obtained with non-instrumented prices.
